

Macroeconomic forecasts at the MoF – a look into the rear-view mirror

The first experimental publication summarizing the past and expected future development of basic economic indicators was published by the MoF in November 1995. The basis was thereby established for a regular publication which has gradually become a source of knowledge for the wider economically literate public in the Czech Republic and abroad.

Sources of tables and graphs: MoF, European Commission, OECD, IMF, MoF's calculations.

Basic terms

The success rate of macroeconomic forecasts is usually evaluated by means of several basic statistics – the average forecasting error, the mean absolute error and Theil's inequality coefficient.

Average forecasting error (AFE) indicates the deviations of forecasts. Positive AFE values indicate systematic or overwhelming overvaluation of forecasts, negative AFE values indicate systematic or overwhelming undervaluation of forecasts. AFE is defined using the following relation:

$$AFE = \frac{\sum_{t=1}^T (F_t - A_t)}{T}$$

, where A_t is the real value over time t , F_t is the forecast for the period t and T is the number of observations.

Mean absolute error (MAE) expresses the average absolute error of the forecast compared to reality. MAE is defined as:

$$MAE = \frac{\sum_{t=1}^T |F_t - A_t|}{T}$$

Theil's inequality coefficient (TIE) is used for evaluating the success rate of forecasts. The coefficient is defined as the proportion of the mean quadratic variations of analyzed forecasts and naive forecasts:

$$TIE = \frac{\sum_{t=1}^T (F_t - A_t)^2}{\sum_{t=1}^T (A_{t-1} - A_t)^2}$$

If Theil's coefficient equals 0, the forecast is identical to reality. Any values of the coefficient higher than 1 show that the results of forecasting activities are worse than a naive forecast. When interpreting the results, it is necessary to take into account the fact that this indicator greatly "penalizes" an isolated considerably worse result compared to the naive forecast, and conversely, it awards a considerable "bonus" in the event of well-estimated sudden reversals in the development of forecast quantities.

The naive forecast is a mechanically drawn up forecast where the value of the given indicator for the year of $t+1$ equals a changed, estimated or forecast value of this indicator for the year t .

The forecast horizon is understood as the time from publishing the forecast until the end of the forecast period. For any horizons above 15 and up to 24 months, it concerns evaluating an outlook (created by means of extrapolation techniques) whose forecasting information is very limited for understandable reasons.

All statistics were calculated against the **first estimates published by the CZSO or CNB**, since it is not possible to estimate the extent of changes in past development through subsequent revisions of time series which cannot usually be divided into components of factual specification of the given ratio and methodological change.

Comparison of the results of MoF's forecasts with forecasts of international institutions

The MoF's forecasts were compared with macroeconomic forecasts of the OECD, the European Commission and the International Monetary Fund for 2001–2012 in the horizons corresponding to their mainly half-yearly publishing cycle. The results show that the **forecast success rate of all institutions does**

not differ much in essence. The best results are mostly achieved by forecasts from the MoF and OECD. The MoF's forecasts are the most precise, especially in terms of nominal GDP growth, GDP deflator growth and average inflation rate.

3 months	0.28	0.22	0.19	0.72	1.02	0.93	0.35	0.62	0.59

Note: As far as consumer prices are concerned, the EC forecasts HICP, which cannot be compared with the national CPI. In the forecasts of the EC, current account balance to GDP ratio is defined in national accounts terms. The IMF forecasts include only the forecasts for real GDP growth, inflation rate and the current account balance to GDP ratio.

Evaluation of the MoF's forecasts

Today, an 18-year history of regular quarterly forecasts provides a high-quality source with which to evaluate their success rate. This can help forecast users get an idea of how precisely the MoF is able to identify the future development of basic macroeconomic indicators across various time horizons.

At the same time it is necessary to realize that during the evaluated period some major changes have occurred in the Czech economy, which was gradually changing from a volatile transition economy to a more or less stabilized market economy in the EU. Since 2008, the Czech economy has been affected by the global recession and the consequences of the subsequent debt crisis in the euro zone, which have manifest themselves in a repeated increase in volatility of macroeconomic indicators. Therefore, we have divided the period 1995–2012 into three six-year

periods of identical length (1995–2000, 2001–2006 and 2007–2012)¹ in order also to be able to evaluate the success rate of forecasts over time.

All macroeconomic forecasts are inherently conditioned by adopted assumptions regarding the development of exogenous factors, of which some, for example natural disasters, the development of financial markets, including commodity prices or changes in the political environment outside and inside the Czech Republic, are inherently unpredictable. Other assumptions, for example the impact of structural policy measures, can only be quantified with great difficulty. Another important source of uncertainty is revisions of databases for past periods, concerning in

¹ Some analyzed indicators have not been included in the Macroeconomic Forecast since the start of publication.

particular those most important indicators of the national accounting system (GDP and its components).

Last but not least, it is necessary to point out the fact that at a time of economic turbulence and financial crises the forecasting of future economic development is considerably more difficult than in a period of stable economic growth.

Real GDP Growth

In 1995–2000 and 2007–2012 the MoF’s forecasts overvalued real GDP growth, with forecasts widest of the mark in 1998, 2009 and 2012, when the Czech Republic was in recession. Conversely, in 2001–2006 when the Czech Republic was going through a period of relatively strong and stable economic growth, GDP growth was slightly undervalued, although this undervaluation did not exceed –0.9 p.p.

In accordance with results published in the literature and based on the experience of forecasters, it has been proved very difficult, even impossible, to identify the onset of a recession in time. In the first and third monitored periods, the mean absolute error exceeded in the horizon over 18 months the limit of 3 p.p., which was caused in particular by the failure to identify recessions in 1998, 2009 and 2012. In the successful period of 2001–2006, the mean absolute error fluctuated below 1.7 p.p. throughout the horizon.

Graph 1: Average Forecasting Error

in p.p., forecast horizon in months on the horizontal axis

Identifying the impacts of those factors emanating externally and which are completely beyond the control of the forecasting team is, however, difficult (if not impossible) and therefore in accordance with literature (see p. 8) we have abstracted away from these facts.

In connection with the so-called great recession at the turn of 2008 and 2009, it is necessary to emphasize, however, that the decline in the domestic economy was caused exclusively by unfavourable development in the external environment. Comparison with the forecasts of other institutions at that time confirms how difficult it was to predict future development.

Theil’s coefficient in the forecast horizon beyond 24 months exceeds 1 on average. However, this gradually decreases with a shortening horizon. The analysis proves that the recognizability of future development in an 18-month horizon exceeds only slightly the possibilities of the naive forecast. It is in this very horizon that the macroeconomic framework of the draft state budget is usually drawn up. This knowledge can also be related to many of the following indicators.

Graph 2: Theil’s Coefficient

forecast horizon in months on the horizontal axis

Nominal GDP Growth

From the perspective of the budget process, the most important macroeconomic indicator is nominal GDP. It is used as the denominator of important ratios (e.g. the government sector's balance or debt as a ratio to GDP) and budget revenue forecasts are derived from the size of its components.

As in the case of real GDP growth, nominal GDP growth was overvalued by forecasts in the first and third periods, although the overvaluation in 2007–2012 was likewise considerably lower. Undervaluation of nominal GDP growth in 2001–2006 was only minimal.

Graph 3: Average Forecasting Error

in p.p., forecast horizon in months on the horizontal axis

GDP Deflator Growth

GDP deflator growth was overvalued in every single monitored period; nevertheless, the average mean error against the actual facts did not exceed 1.5 p.p. throughout the horizon.

The average mean absolute error did not exceed 2 p.p., and reached its highest values in 1995–2000. The decreasing trend is also confirmed by the graph showing absolute error in the 18-month horizon. The error for 1999 relates to the period of disinflation,

Graph 5: Mean Absolute Error

in p.p., forecast horizon in months on the horizontal axis

In the 18-month horizon representing the starting point for drafting the state budget, the mean absolute error for the whole period reached approximately 3 p.p., although it shows a decreasing tendency. Its high values in 1997, 2009 and 2012 were recorded for periods of economic recession, the year 1999 relates to a period of disinflation. The average value of Theil's coefficient in the forecast horizon up to 27 months is lower than 1, while it reaches its lowest values in 2001–2006.

Graph 4: MAE in the 18-Month Horizon

in p.p., the forecasted year on the horizontal axis

when GDP deflator growth decreased from 10.7% in 1998 to 2.4% in 1999. Although a decrease was expected and identified correctly in time, its extent exceeded all expectations.

The average Theil's coefficient did not exceed the value of 1.0 throughout the horizon. In the horizon up to 21 months its values decreased gradually in individual periods, thereby highlighting the improvement of forecasts.

Graph 6: MAE in the 18-Month Horizon

in p.p., the forecasted year on the horizontal axis

Real Private Consumption Growth

While in the first and third monitored periods growth in household consumption was overvalued, in the second period forecasts were slightly tilted to the downside.

The mean absolute error in individual periods reaches approximately the same values as in case of forecasts of real GDP growth. In the horizon of 2–3 years, it is approximately 3 p.p. on average, whereupon it gradually decreases and drops below 1.5 p.p. within a short period of up to one year.

The absolute error in the 18-month horizon shows an increasing tendency. However, this result is strongly influenced by the imprecise estimate of household consumption in 2012. The extremely low level of

consumer confidence in future economic development, together with the implementation of the government's austerity measures, led to cautious behaviour on the part of consumers and to an increase in the rate of savings as a precaution against any further worsening of the economic situation. Thus the decrease in household consumption by 3.5% in 2012 exceeded all expectations. After all, in 2009 during the recession household consumption had even increased by 0.2%!

The average value of Theil's coefficient fluctuated below 1.0 in the horizon up to 18 months. However, in 2007-2012 the coefficient reached considerably higher values than in the other two periods, which was caused in particular by imprecise estimates in 2009 and 2012.

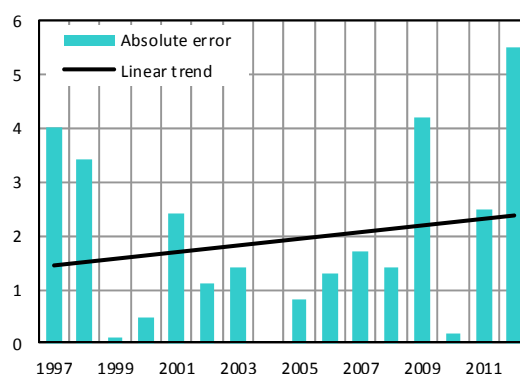

Graph 7: Average Forecasting Error

in p.p., forecast horizon in months on the horizontal axis

Graph 8: MAE in the 18-Month Horizon

in p.p., the forecasted year on the horizontal axis

Average Inflation Rate

Forecasts of inflation in the Macroeconomic Forecast were precise in most cases, since in the horizon up to 30 months the average forecasting error did not exceed 1 p.p. for the whole monitored period. In 1995–2000 and 2001–2006, forecasts slightly overvalued the average inflation rate, while in the second period the overvaluation was higher. Conversely, in 2007–2012 the average mean error achieved negative values, although it did not fall below –0.5 p.p. in any of the horizons.

In the horizon up to 30 months, the mean absolute error did not exceed 2 p.p. In the budget horizon of

18 months the mean absolute error has a decreasing tendency. The error for 1999 relates to a period of severe disinflation, when the average inflation rate fell from 10.7% in 1998 to 2.1% in 1999. Although this tendency was identified correctly, its extent exceeded all expectations. The fact that in the budget horizon of 18 months the absolute error did not exceed 1.0 p.p. in 10 out of the 16 monitored years is testimony to the precision of inflation forecasting.

Theil's inequality coefficient for all monitored periods did not exceed 0.85 in the whole time horizon and was 0.15 in the short 1-year period.

Graph 9: Mean Absolute Error

in p.p., forecast horizon in months on the horizontal axis

Average Unemployment Rate (LFS)

The unemployment rate according to LFS has only been forecast since 2000, so any comparison of the quality of forecasts over time was possible only for the periods of 2001–2006 and 2007–2012.

The forecasts systematically overvalued the unemployment rate, still the average mean error did not exceed 1.0 p.p. in any time horizon. In 2007–2012, the overvaluation compared to the previous period was considerably lower: the average mean forecasting error did not exceed 0.55 p.p. in any horizon.

The average mean absolute error showed a gradually decreasing tendency. Nonetheless, in 2007–2012 it reached higher values due to the difficulty in forecasting at a time of economic instability compared

Graph 11: Average Forecasting Error

in p.p., forecast horizon in months on the horizontal axis

Graph 10: MAE in the 18-Month Horizon

in p.p., the forecasted year on the horizontal axis

to the previous period. In the 18-month budget horizon, the mean absolute error has an increasing tendency with respect to imprecise estimates in 2009 and 2007. In 2009, the unemployment rate was undervalued when as a result of the economic recession it increased by 2.3 p.p. compared to the previous year. On the other hand, in 2007 the unemployment rate was overvalued, since strong economic growth resulted in its decrease down to 4.4%. Data for 2004 are missing due to a change in methodology.

These imprecise estimates are also reflected in the higher average value of Theil's coefficient, which exceeds the value of 1.0 in the horizon of 33, 21 and 18 months.

Graph 12: Mean Absolute Error

in p.p., forecast horizon in months on the horizontal axis

Current Account Balance to GDP Ratio

During the monitored period, the forecasts overvalued the ratio of the current account balance to GDP. However, the average forecasting error did not exceed 0.5 p.p. on average. The average mean absolute error was between 1 and 2 p.p. in the horizon of 6–24 months, while it was usually the lowest in the third monitored period. Absolute error in the 18-month horizon has a decreasing character.

Except for the horizon of 15 months, the average for Theil's coefficient was lower than 1. However, it

Graph 13: Average Forecasting Error

in p.p., forecast horizon in months on the horizontal axis

reached its lowest values in the first period, while in 2007–2012 it was even higher than 1 in the horizon of 6–18 months. This phenomenon can largely be attributed to a change in the system of revisions. While revisions were previously ongoing, now they occur only once a year. Consequently, the period in which the forecast is based on subsequently revised data is extended.

Graph 14: Mean Absolute Error

in p.p., forecast horizon in months on the horizontal axis

Conclusion

Assessment of the history of the MoF's Macroeconomic Forecasts has showed that they are fully comparable to the forecasts of renowned international institutions, and in a number of cases even surpass them. The MoF usually publishes its forecasts earlier than the other institutions included in this comparison.

Based on the conducted analysis it is possible to say that for most macroeconomic indicators forecasts contain valid data in a horizon of approximately up to 18 months. In longer horizons, however, the objective is geared more towards determining the expected trends of economic development.

As far as the development of forecast precision over time is concerned, it is apparent that forecast precision increased in the second and third monitored periods (2001–2006, 2007–2012) compared to the first period (1995–2000). In this context, however, it must be pointed out that forecasting future economic development is considerably more difficult at a time of economic crisis and recession than in a period of stable economic growth. This fact was the main reason for several imprecise forecasts in 2007–2012.
